ABSTRACT: Since elevated ethanol is a major stress during ethanol fermentation, yeast strains tolerant to ethanol are highly desirable for the industrial scale ethanol production. A technology called global transcriptional machinery engineering (gTME), which exploits a mutant library of *SPT15* encoding the TATA-binding protein of *Saccharomyces cerevisiae* (Alper et al., 2006; Science 314: 1565–1568), seems to a powerful tool for creating ethanol-tolerant strains. However, the ability of created strains to tolerate high ethanol on rich media remains unproven. In this study, a similar strategy was used to obtain five strains with enhanced ethanol tolerance (ETS1–5) of *S. cerevisiae*. Comparing global transcriptional profiles of two selected strains ETS2 and ETS3 with that of the control identified 42 genes that were commonly regulated with twofold change. Out of 34 deletion mutants available from a gene knockout library, 18 were ethanol sensitive, suggesting that these genes were closely associated with ethanol tolerance. Eight of them were novel with most being functionally unknown. To establish a basis for future industrial applications, strains iETS2 and iETS3 were created by integrating the *SPT15* mutant alleles of ETS2 and ETS3 into the chromosomes, which also exhibited enhanced ethanol tolerance and survi-

val upon ethanol shock on a rich medium. Fermentation with 20% glucose for 24 h in a bioreactor revealed that iETS2 and iETS3 grew better and produced approximately 25% more ethanol than a control strain. The ethanol yield and productivity were also substantially enhanced: 0.31 g/g and 2.6 g/L/h, respectively, for control and 0.39 g/g and 3.2 g/L/h, respectively, for iETS2 and iETS3. Thus, our study demonstrates the utility of gTME in generating strains with enhanced ethanol tolerance that resulted in increase of ethanol production. Strains with enhanced tolerance to other stresses such as heat, fermentation inhibitors, osmotic pressure, and so on, may be further created by using gTME. Biotechnol. Bioeng. 2011;108: 1776–1787.

Introduction

During ethanol production, ethanol-producing microorganisms confront multiple stresses such as high initial substrate concentration, increased ethanol concentration, and accumulation of toxic byproducts. In addition to rapid growth and efficient fermentation capacity, the ability to tolerate these stresses is an important factor in choosing an

Additional Supporting Information may be found in the online version of this article.

ethanol producer (Ding et al., 2009; Gibson et al., 2007; Zhao and Bai, 2009). *Saccharomyces cerevisiae* has been used as a primary microorganism for ethanol production on an industrial scale. The accumulation of ethanol to toxic concentrations during fermentation is the major stress that causes reduced ethanol production and eventual stuck fermentations (Gibson et al., 2007). Thus, the development of *S. cerevisiae* strains that can endure ethanol stress is both prudent and important. One way to address such an issue is to understand the mechanisms underlying ethanol stress tolerance. For this, two different molecular approaches have recently been used to identify genes involved in ethanol tolerance: genome-wide DNA microarray analysis (Alexandre et al., 2001; Chandler et al., 2004; Dinh et al., 2009; Hirasawa et al., 2007; Marks et al., 2008; Rossignol et al., 2003; Varela et al., 2005; Wu et al., 2006) and screening of single gene knockout (SGKO) libraries (Fujita et al., 2006; Kubota et al., 2004; Yazawa et al., 2007; Teixeira et al., 2009; van Voorst et al., 2006; Yoshikawa et al., 2009). However, the issue with these two approaches is that a huge number of target genes have been identified, representing as much as 5–10% of genes encoded in the yeast genome and that few successful examples have been documented (Hirasawa et al., 2007; Yazawa et al., 2007).

An alternative approach to develop ethanol-tolerant strains (ETs) is global transcriptional machinery engineering (gTME). This approach was first used to create a strain with enhanced ethanol tolerance by generating mutations of TATA-binding protein encoded by *SPT15*, which could grow at a formerly lethal ethanol concentration (Alper et al., 2006). However, other authors reported that this enhanced ethanol tolerance was not reproduced on a rich medium (Baerends et al., 2009), which is not optional for industrial applications.

Nevertheless, *SPT15* mutations altered the transcription profile (Alper et al., 2006). In addition, *SPT15* mutations were pleiotropic (Eisenmann et al., 1989) and some mutations in the regulatory domain of *SPT15* resulted in transcriptional increase (Cang et al., 1999). These observations indicate that different mutations of *SPT15* may induce expression of different sets of genes. It was of our concern whether point mutations different those introduced by Alper et al. (2006) could enhance ethanol tolerance on a rich medium. In this study, five ETs containing different *SPT15* mutant alleles were obtained and the effect of *SPT15* mutations on ethanol production was examined, re-emphasizing the usefulness of gTME as a tool for creating strains tolerant to ethanol and hopefully to other various stresses.

Materials and Methods

Yeast Strains and Media

S. cerevisiae L3262 (*MAT-α; ura3-52 leu2-3,112 his4-34*) and BY4741 (*MATa his3Δ1 leu2Δ0 met15Δ0 ura3Δ0*) were

used as transformation recipients. The non-essential haploid *S. cerevisiae* deletion library was used for the verification of identified genes. Unless otherwise mentioned, yeast cells were grown at 30°C in YPD (1% yeast extract, 2% peptone, 2% glucose, and 1.5% agar for solid plates) for non-selective propagation or yeast synthetic complete (YSCD) medium (0.67% yeast nitrogen base without amino acids, amino acid supplement mixture, 2% dextrose, and 1.5% noble agar for solid plates) for selective propagation.

Molecular Methods

Plasmid preparation, cloning, and sequencing were performed as previously described (Sambrook and Russell, 2001). *Escherichia coli* strain DH5α was used as a host for plasmid preparation.

Reverse Transcription–Polymerase Chain Reaction (RT–PCR) and PCR

For RT, total RNA was prepared from exponentially growing cells. First strand cDNAs were synthesized by transcribing 2 μg of total RNAs with random hexamers and 200 U of M-MuLV reverse transcriptase (Promega, Madison, WI) as recommended by the manufacturer. Oligonucleotides used for PCR are listed in Supplementary Table I. The amplification conditions were 95°C for 1 min, 55–60°C for 1 min, and 72°C for the appropriate period of time depending on the length of DNA to be amplified for 20 cycles for RT-PCR and 30 cycles for regular PCR. If necessary, PCR products were purified by gel elution, cloned into the pGEM-T easy vector (Promega), and sequenced.

SPT15 Mutant Library Construction

The open reading frame (ORF) of *SPT15*^{wt} was PCR-amplified from genomic DNA as a template with primers SPT15ORF-S and SPT15ORF-AS and cloned into the pGEMT-easy vector (Promega), yielding pT-*SPT15*. The *SPT15* mutant library was generated by using the GeneMorph II random mutagenesis kit (Stratagene, La Jolla, CA) with pT-*SPT15* as template and using the aforementioned primers. PCR products were digested with *Bam*HI and *Eco*RI, and cloned into a pRS316-derived plasmid, pRS316-GCYH2gR, in which cloned genes are placed under control of glyceraldehyde-3-phosphate dehydrogenase promoter (*TDH3*_p) and galactose-1-phosphate uridyl transferase terminator (*GAL7*_T). The resulting plasmids were transformed into *E. coli* DH5α and incubated at 30°C (to prevent outgrowth of fast-growing cells) to generate a primary library for *SPT15* mutants with total colony number being 4×10^6 . From the sequencing of 20 randomly selected colonies, the molecule-based mutation rate was determined to be 70%. Mutations were found at more than one site, mostly 3–5, in 14 colonies, with the remainder being the wild type. One of these wild-type

plasmids was used as the control vector (pSPT15wt). Following amplification and large-scale preparation, the library plasmids (500 µg) were transformed into *S. cerevisiae* L3262 and incubated at 25°C (to prevent outgrowth of fast-growing cells) on solid YSCD–Ura. The total number of yeast colonies was approximately 5×10^6 with a transformation efficiency of approximately 1×10^4 colony forming units (CFU)/µg DNA. All the colonies were harvested by scrubbing the surfaces of plates with 15 mL YSCD–Ura to prepare a yeast library for *SPT15* mutants. After fourfold propagation in cell number at 25°C, aliquots of the cell suspension were stored at –80°C in the presence of 20% glycerol until used.

Yeast Transformation

All plasmids for yeast transformation were manually prepared without RNA digestion. The DNA concentration was roughly measured by comparing the band intensity with that of control DNA of known concentration. This mixture of DNAs and RNAs was used for yeast transformation as previously described (Gietz and Woods, 2002).

Spot Assay and Ethanol Susceptibility Assay

For spot assay, aliquots (5 µL) of cells grown to an optical density at 600 nm (OD_{600}) of 1.0 were tenfold serially diluted and spotted onto solid synthetic or rich media containing appropriate concentrations of ethanol. Plates were incubated at 30°C for 4–6 days.

For ethanol susceptibility assay, Cells grown to OD_{600} of 1.0 were harvested, equally divided into fresh YSCD–Ura media containing 12.5% and 15% ethanol (v/v), and incubated at 30°C for 4–6 h. At appropriate time points, aliquots were properly diluted and plated onto solid YPD. Cell viability was measured as a function of time and expressed as the relative number of CFU.

Transcriptome Profiling and Data Analysis

S. cerevisiae 30K oligo microarrays (MYcroarray, Ann Arbor, MI) were used for transcriptome profiling. Total RNA was prepared from exponentially growing cells and RNA quality control for microarray analysis were performed as described previously (Park et al., 2007). cDNAs incorporated with aminoallyl-dUTP were synthesized from 40 to 50 µg of total RNA using an Aminoallyl post DNA Labeling kit (GeneChem, Daejeon, Korea) and a superscript reverse transcriptase (Invitrogen, Carlsbad, CA). The synthesized cDNA was labeled with NHS-ester Cy dyes and used for hybridization. Hybridized slides were washed by SSC buffer, and then scanned with a ScanArray 5000 scanner (Hewlett-Packard, Palo Alto, CA). Raw microarray data were analyzed by using ArrayNorm (<http://genome.tugraz.at/>), a platform-independent Java tool for normalization and statistical analysis (Pieler et al., 2004). Clustering for genes with

the average change higher than twofold was carried out using Cluster 3.0 (<http://rana.lbl.gov/EisenSoftware.htm>). Enrichment of functional categories among differentially expressed genes was analyzed using the MIPS Functional Catalogue (<http://mips.gsf.de>). Specific gene functions were based on the *Saccharomyces* Genome Database (<http://www.yeastgenome.org>), and transcription factor-binding sites were analyzed by YEASTRACT (<http://www.yeasttract.com/index.php>). To validate DNA microarray data, semi-quantitative reverse transcription PCR was performed as described previously (Oh et al., 2004) with the RNA samples used for microarray experiments.

Genomic Integration

The DNA fragments covering the *TDH3p*, *ORF*, and *GAL3T* were excised from pSPT15wt, pSPT15-M2, and pSPT15-M3 and cloned into the integrating vector pRS406. The resulting plasmids were linearized with *ApaI* and transformed into *S. cerevisiae* L3262. Genomic integration was verified by PCR with primer sets shown in Supplementary Table 1.

Fermentation

Ethanol fermentations were performed at 30°C with cells initially adjusted to an OD_{600} of ~1.0 in 500 mL YPD20 (2% peptone, 1% yeast extract, 0.02% $(NH_4)_2SO_4$, and 20% glucose) in 1-L bioreactor with pH maintained at 5.5 and oxygen supplied at 200 mL/min. The cultures were agitated at 400 rpm with antifoaming agent added. Samples were collected at appropriate time points and analyzed for concentration of glucose, ethanol, and glycerol produced during fermentation by performing high-pressure liquid chromatography (HPLC). The samples were loaded onto Aminex HPX-87H column (Bio-Rad, Hercules, CA) set to 60°C and eluted with 0.5 mM H_2SO_4 at a constant flow rate of 0.6 mL/min. Peaks were detected by a refractive index detector and quantified according to a calibration curve for each of glucose, ethanol, and glycerol molecules. Cell growth was monitored by measuring the OD_{600} with appropriate dilutions.

Results

Identification of Ethanol-Tolerant Strains

To obtain ETSs by screening of a yeast *SPT15* mutant library constructed in the present study, 5×10^6 colony forming units were spread on the solid YSCD–Ura medium supplemented with 12.5% ethanol and incubated at 30°C. Seven days after, 15 colonies had developed in the presence of 12.5% ethanol. The ethanol tolerance of the 15 colonies was examined by a spot assay on the solid YSCD–Ura medium containing up to 15% ethanol. As a result, five ETSs (ETS1–5) were obtained. All five strains tolerated 15% ethanol, whereas the control did not tolerate ethanol concentrations exceeding 10% (Fig. 1).

Figure 1. Enhanced ethanol tolerance of ETS1-5. Cells were grown to an OD600 of 1.0 in the YSCD-Ura or YPD liquid media and tenfold serially diluted. Aliquots (5 μ l) were spotted onto YSCD-Ura or YPD plates containing appropriate concentrations of ethanol and incubated at 30°C for 4–6 days. Control strain (C-L3262) was constructed by transformation of pSPT15wt into L3262.

To confirm whether the enhanced ethanol tolerance was conferred by the presence of a mutated *SPT15*, plasmids were recovered from ETS1–5 (pSPT15-M1, -M2, -M3, -M4, and -M5, respectively). Sequencing of each *SPT15* allele-located mutations in the *SPT15* ORF: K201N, G216S, and N225Stop in *SPT15-M1*; L76V and L175S in *SPT15-M2*; S42N, C78R, S163P, and I212N in *SPT15-M3*; F10S and M197K in *SPT15-M4*; K15T, W26C, and G192D in *SPT15-M5* (Fig. 2). A silent mutation (N225Stop) in *SPT15-M1* yielded a truncated version with 16 residues deleted at the C-terminus. No particular point mutation was common, although one or two residues were changed in the repeat element 2 of all alleles. This element contains the domain interacting with Spt3p (amino acid residues 172–179), which has been implicated in the regulation of gene transcription (Alper et al., 2006; Cang et al., 1999). Overall, these data were consistent with the suggestion that the mutation of several subregions of Spt15p confers ethanol

tolerance, presumably through the interaction with other components of the transcriptional machinery in addition to Spt3p (Eisenmann et al., 1989).

Each plasmid was re-introduced into L3262 and BY4741 to yield rL-ETS1–5 and rBY-ETS1–5. pRS316-GCYH2gR containing wild-type *SPT15* (*SPT15wt*) was transformed into L3262 and BY4741, yielding control strains C-L3262 and C-BY4741. When spot-assayed on a synthetic medium, rL-ETS1–5 showed the same degree of ethanol tolerance as ETS1–5 did (Fig. 3, top panel). Meanwhile, rBY-ETS1–5 showed tolerance to as high as 17.5% ethanol (Fig. 3, bottom panel). This was not surprising, since BY4741 originally displayed higher ethanol tolerance than L3262 (data not shown). Thus, the enhanced ethanol tolerance of ETS1–5 was suggested to be the effect of mutated *SPT15*.

Based on the above spot assay results in which ETS2 and ETS3 were slightly more tolerant than the remainder, these two were chosen for DNA microarray, testing the ability to

Figure 2. Schematic representation of mutated *SPT15* alleles. Plasmids (pSPT15-M1–5) were recovered from ETS1–5 and sequenced. Comparison of the deduced amino acid sequence with *SPT15wt* locates the position of point mutations (arrows). The map of structural domains is based on the previously published literature (Alper et al., 2006).

Figure 3. Confirmation of enhanced ethanol tolerance. Plasmids pSPT15-M1–5 were re-transformed into L3262 and BY4741, yielding rL-ETS1–5 and rBY-ETS1–5, respectively. Control stain C-BY4741 was constructed by transformation of pSPT15wt into and BY4741. Spot assay was performed as in Figure 1.

grow on a rich medium, and genome integration of *SPT15* alleles.

Transcriptome Profile Analysis of Ethanol-Tolerant Mutant Strains

We were interested in genes responsible for enhanced ethanol tolerance of ETS2 and ETS3, the expression levels of which were regulated by *SPT15* mutations. To obtain this information, DNA microarrays for transcriptional profiling were conducted with total RNAs prepared from control C-L3262, ETS2, and ETS3 cells grown to early-log phase in YSCD-Ura. After performing microarray experiments in duplicate, expression fold changes were averaged. The raw data have been registered at Gene Expression Omnibus under the accession number GSE23965. The level of *SPT15* increased eightfold on average in both ETS2 and ETS3 (data not shown). Clustering of genes with fold change higher than two compared to control displayed differential expression patterns between ETS2 and ETS3, reflecting the effect of different mutations of *SPT15* on the global transcription (Fig. 4A). To validate the microarray data, the actual expression levels of *HSP30*, *HSP42*, and *HSP104* were examined by RT-PCR. According to the microarray data,

HSP30, *HSP42*, and *HSP104* were up-regulated by 5.7-, 4.3-, and 1.7-fold in ETS2 and 6.3-, 4.1-, and 1.8-fold in ETS3, respectively. The fold increases of those genes were consistent with the RT-PCR data (Fig. 4B).

In ETS2, 45 and 11 genes were up- and down-regulated, respectively, whereas in ETS3, 79 and 21 genes were up- and down-regulated, respectively (Fig. 4C). Thirty-four up-regulated and eight down-regulated genes were shared between ETS2 and ETS3 (Fig. 4C). To gain further information on the transcriptional regulation of commonly up- and down-regulated genes, we examined the presence of putative binding sites for transcription factors presumed to be involved in various stress responses, such as Msn2p/Msn4p for general stress (Watanabe et al., 2007), Hac1p for protein secretion stress (Ogawa and Mori, 2004), Hsf1p for heat stress (Yamamoto et al., 2008), and Yap1p for oxidative stress (He and Fassler, 2005). Quite intriguingly, the binding sites for these transcription factors were highly enriched in the upstream regions of commonly up-regulated genes (Table I). Particularly, the binding sites for Msn2p/Msn4p were found in nearly all of commonly up-regulated genes. Meanwhile, the binding sites for Msn4p/Msn2p and Yap1p were found far less frequently, in contrast to similar frequencies for Hac1p and Hsf1p, in the eight commonly down-regulated genes. The collective data suggests that

Figure 4. Microarray data analysis of ETS2 and ETS3. Microarray analysis was performed with Poly+ (A). RNAs prepared from C-L3262 (control), ETS2, and ETS3 grown to mid-log phase without ethanol stress challenge. Differentially expressed genes with expression fold change >2 were profiled for clustering; I, down-regulated genes, II, up-regulated genes. B: Microarray data were validated by semi-quantitative RT-PCR of Hsp30, Hsp42, and Hsp104. Numerals 1 and 2 indicate independent duplicates. C: control (L3262) (C) Venn diagram of up- and down-regulated genes in ETS2 and ETS3. D: Ethanol sensitivity of SGKO mutants. Individual clones corresponding to 30 commonly up-regulated in ETS2 and ETS3 were retrieved from the BY4741 SGKO library. Spot assay was performed as in Figure 1. The parental strain BY4741 was used as a control. Cells were cultured in liquid YPD and spotted on solid YPD containing 0%, 6%, 8%, 10%, and 12% ethanol, and incubated at 30°C for 1–6 days. [Color figure can be seen in the online version of this article, available at <http://wileyonlinelibrary.com/bit>]

Msn4p/Msn2p and Yap1p may be responsible for the regulation of genes associated with ethanol tolerance.

Effect of Commonly Regulated Genes on Ethanol Tolerance

Of concern was whether the 34 commonly up-regulated and eight commonly down-regulated genes were a cause or an effect of ethanol tolerance. If the up-regulation of a gene-enhanced ethanol tolerance, it would be highly likely that its deletion would render cells sensitive to ethanol. The reverse would be the case for the down-regulated genes. Deletion mutants corresponding to 30 up- and 6 down-regulated genes were retrieved from the BY4741 SGKO collection. Those corresponding to four up-regulated genes (YER053C-A, YNR034W-A, YPR145C-A, YBL029C-A) and two down-regulated genes (RRN7 and YOR387C) were not available, probably due to their lethality. BY4741 as control and individual deletion mutants grown to an OD₆₀₀ of 0.5 were diluted tenfold and spotted on solid YPD medium containing several different concentrations of ethanol.

The results for 30 deletion mutants corresponding to commonly up-regulated genes are shown in Figure 4D. Some deletion mutants were sensitive to as low as 6%, far below the concentration that exerts toxic effect to BY4741. It was natural that total number of sensitive mutants increased as the ethanol concentration increased up to 12%. Sensitivity to 6% ethanol corresponded to deletions in *GPH1*, *SOL4*, and *SSA4*. An additional seven mutants (*ALD3*, *BTN2*, *SPI1*, *OM45*, *RTC3*, *USV1*, and *YFR017C*)

were sensitive to 8% ethanol. The *HSP12* deletion mutant was sensitive to 10% ethanol. Finally, deletions in *HSP30*, *CTT1*, *STF2*, *AIM17*, *FMP16*, *RGII*, and *PHM8* rendered mutants sensitive to 12% ethanol. Thus, deletion of 18 out of 30 genes commonly up-regulated in ETS2 and ETS3 conferred ethanol sensitivity. Of these, eight genes (*ALD3*, *BTN2*, *OM45*, *RTC3*, *USV1*, *YFR017C*, *FMP16*, and *PHM8*) have never been reported in association with ethanol tolerance or induction upon ethanol shock. Since these genes were identified by combination of DNA microarray and deletion assays, the probability that these genes are involved in the enhanced ethanol tolerance is higher than those identified by either assay. Meanwhile, none of six deletion mutants corresponding to commonly down-regulated genes displayed enhanced growth (data not shown), contrary to our expectation that some of them would display higher degree of ethanol tolerance than the control.

Construction of Genome-Integrated Strains

As shown above, episomal overexpression of mutated *SPT15* conferred enhanced ethanol tolerance to cells grown on a synthetic medium. To extend these results to the development of industrial strains, of great concern was whether or not the enhanced ethanol tolerance was sustained in both cells grown on a rich medium and cells with mutated *SPT15* alleles integrated into the genome. It has been argued that low leucine supplementation, but not mutated *SPT15*, led to enhanced ethanol tolerance (Baerends et al., 2009). More

Genes showing more than twofold change are listed. Genes whose deletion renders cells sensitive to ethanol are in bold (Fig. 4). Of these, genes that have never been reported are underlined.

significantly, ethanol tolerance was abolished when cells were cultured in the YPD-rich medium, which is not optional for industrial applications. Since ETS2 and ETS3 are leucine auxotrophs, the enhanced ethanol tolerance of these strains might not be due to mutations in *SPT15*. However, ETS2 and ETS3 sustained ethanol tolerance on YPD as shown in Figure 5A.

The cell–cell heterogeneity in expression is one of issues encountered when the information obtained from episomal overexpression in laboratory strains is scaled up to industrial applications. Heterogeneity is caused by the inability to control copy number in spite of the continual presence of selection pressure, which clearly is not optional for yeast culture on an industrial scale. Accordingly, stable expression and maintenance of the gene in the absence of selective pressure (i.e., integration into the chromosome) is frequently desirable. Here, we constructed strains in which *SPT15-M2* and *-M3* were integrated into the genome of L3262; the corresponding constructs were named iETS2 and

iETS3, respectively. The control strain iL3262 were created with a plasmid containing *SPT15wt*. Figure 5B shows that iETS2 and iETS3 displayed enhanced ethanol tolerance on YPD.

To confirm the spot assay results, the susceptibility to 12.5% and 15% ethanol was examined for iETS2 and iETS3 (Fig. 5C). At 12.5% ethanol, the timepoint showing 50% viability (T_{50}) was 4.5 h for iETS2 and iETS3, in contrast to 3.5 h for the control. A sharper contrast was observed at 15% ethanol, with a T_{50} of 100 min for both iETS2 and iETS3, and 40 min for control. Thus, we obtained two integrated strains with enhanced ethanol tolerance on a rich medium.

The Effect of Mutated *SPT15s* on Ethanol Production

Our next concern was to investigate the relevance of enhanced ethanol resistance of iETS2 and iETS3 (compared to control iL3263) to improvement of ethanol production

Figure 5. Ethanol tolerance of episomal and integrated ETS2 and ETS3 on YPD. **A:** Spot assay of ETS2 and ETS3 on the YPD plate. **B:** The parental plasmid and plasmids recovered from ETS2 and ETS3 were integrated into the genome of L3262, yielding iL3262, iETS2, and iETS3, respectively. The spot assay was performed on the YSCD–Ura (top panel) and YPD plates (bottom panel). **C:** Ethanol susceptibility of iETS2 and iETS3. Following ethanol shock for the indicated times, iL3262 (●), iETS2 (■), and iETS3 (▲) were grown on the YSCD–Ura plate in the presence of 12.5% and 15% ethanol for 4–6 h. Relative viability was expressed as percentage after counting the number of colony. Experiments were done in triplicate.

under a certain condition. During the 24-h-long ethanolic fermentations performed in YPD20 media as described in Materials and Methods section, the cell growth and ethanol productivity of iL3262 (control), iETS2, and iETS3 were examined (Fig. 6). Three strains grew at the same rate until 4 h timepoint (Fig. 6A), at which the ethanol concentration in the medium was below 1% (Fig. 6B), and then iETS2 and iETS3 grew faster than control, indicating that such low concentration of ethanol started to affect the cell growth. The growth of control seemed to cease at 16 h timepoint

where the ethanol concentration was 5.8%, while iETS2 and iETS3 continued to grow for 4 h or longer, yielding significant differences in OD₆₀₀. At 24 h timepoint where glucose added was almost completely consumed, the final amounts of ethanol were 77 g/L for both iETS2 and iETS3 and 61.5 g/L for control. The ethanol yield for iETS2 and iETS3 (0.39 g/g) was increased by 26% from 0.31 g/g for control. The low ethanol yield by control might be due to the strain specificity. The ethanol productivity of iETS2 and iETS3 was substantially enhanced by 23% (from 2.6 to 3.2 g/L/h), although the specific ethanol productivity (g ethanol/g cell/h) of the control strain was higher than iETS2 and iETS3 due to much less growth of control (~10 OD₆₀₀) compared with iETS2 and iETS3 (~20 OD₆₀₀, Fig. 6A). The less ethanol production in spite of higher specific ethanol productivity of control was presumed to result from the cease of cell growth at 16 h timepoint, where the ethanol concentration was approximately 5.8% (Fig. 6B). The less cell mass and lower ethanol yield by control during fermentation seem to be attributed at least in part to relatively higher conversion of glucose to glycerol starting from 12 h time point at which the ethanol concentration was approximately 3.5% (Fig. 6C). These data together suggest that the ethanol concentration of as low as 1% negatively affects the cell growth and 3.5% ethanol is enough to change the glucose metabolism in iL3262, and further that iETS2 and iETS3 overcome these adversities in favor of efficient ethanol production by the enhanced ethanol tolerance conferred by mutated *SPT15* alleles.

Discussion

The development of ethanol-tolerant *S. cerevisiae* strains is of great economic value for brewing and beverage industries, and the manufacture of bioethanol. The organism-based traditional approaches, such as evolutionary adaptation, random chemical mutagenesis, and gene shuffling, have shed little light on the understanding of the molecular mechanisms of ethanol tolerance. Over the past decade, DNA microarray and SGKO library screening have been extensively exploited to identify genes that are presumed to be associated with ethanol tolerance. Still, the mechanism of ethanol tolerance remains largely unknown. In the meantime, several ethanol strains have been developed by gene manipulations, including a few successful cases based on the data from DNA microarray (Hirasawa et al., 2007) and SGKO library screening (Yazawa et al., 2007), and overexpression of sonicated genomic fragments (Hong et al., 2010). Several strategies identified 18 autologous and two heterologous genes whose deletion, disruption, depletion, or overexpression to the parental cells (Supplementary Table 2). In the present study, 18 genes whose up-regulation is very likely to confer ethanol tolerance were identified by the combined use of DNA microarray and SGKO library screening from two ETs constructed by overexpression of two different *SPT15* mutant alleles *SPT15-M2* and *-M3* (Fig. 4A).

Figure 6. Fermentation kinetics of engineered strains. Overnight yeast cells of control iL3262 (circle) and two ethanol-tolerant strains, iETS2 (square) and iETS3 (triangle), were harvested and transferred to a 1-L bioreactor containing 500 mL of YPD20 (2% peptone, 1% yeast extract, 0.02% (NH₄)₂SO₄, and 20% glucose) with the initial cell density adjusted to OD₆₀₀ of 1.0. Ethanolic fermentations were performed as described in Materials and Methods section. Samples were taken at 4 h intervals to measure the optical density for cell growth (A) and to determine the concentrations of glucose (B, open), ethanol (B, closed), and glycerol (C) by using HPLC. Experiments were done in triplicate.

Intriguingly, none of the autologous genes conferring tolerance by overexpression overlapped with the 18 genes, suggesting that the ethanol tolerance associated with those genes is independent of that resulting from the overexpression of both *SPT15-M2* and *-M3*.

Prior to the advent of the DNA microarray, the DNA filter array analysis identified six genes (*GPD1*, *CTT1*, *HSP12*, *Sp11*, *TPS1*, and *TPS2*) up-regulated in an ethanol-tolerant sake strain compared to the parental strain cultivated free from ethanol stress (Ogawa et al., 2000). Since then, DNA microarray, which has identified a large number of candidate genes associated with ethanol tolerance by comparing the expression profiles of controls (C) and the same cells challenged with ethanol (e-C) under varied conditions. A recent elaborate study (Ma and Liu, 2010a,b) compared the quantitative transcription dynamics of 175 selected genes presumed to be related to ethanol tolerance between C and e-C, between C and T_i (isogenic ETS), and between C and e- T_i (T_i challenged with ethanol), and revealed significant variation in gene activities depending on the comparison set and sampling timepoint. The results of these and other studies and the present study are summarized in Table II. Ma and Liu (2010b) also showed that all 34 genes of e-C overlapped with e- T_i and six genes (*HSP31*, *IRC15*, *ADH1*, *ADH2*, *ADH3*, and *ADH7*) were common between T_i and e- T_i . These data imply that ethanol challenge induces a similar set of genes regardless whether a strain is ethanol tolerant or not, and that the expression profile of an unchallenged ETS is considerably different from that of challenged ETS. We propose that ethanol

tolerance should be dealt with separately from ethanol induction. In fact, *PUT1*, *ATH1*, and *NTH1*, which confer ethanol tolerance when deleted or disrupted (Supplementary Table 2), were up-regulated upon ethanol induction (Ma and Liu, 2010b): sixfold in e-C and fivefold in e- T_i for *PUT1*; 2.2-fold in e- T_i for *ATH1*; 2.0-fold in e-C and 2.7-fold in e- T_i for *NTH1*. Among the genes constitutively up-regulated in four ETSs (SR4-3, Y50316, ETS2, and ETS3), only three genes (*CTT1*, *HSP12*, and *SPI1*) were common between SR4-3, ETS2, and ETS3. Considering the methods employed for developing the strains used for each assay (i.e., breeding for SR4-3, adaptation evolutionary engineering for Y50316, and gTME for ETS2 and ETS3), ethanol tolerance may be achieved by several independent routes in *S. cerevisiae*.

When the construction of a strain with enhanced high glucose and ethanol tolerance by exploiting gTME was reported (Alper et al., 2006), this technique seemed to be a promising approach to directly reveal multiple stress tolerance. Such genetic traits were claimed to be conferred by a specific *SPT15* mutant allele (*SPT15-300*), which resulted from reprogramming of the global gene expression. However, no follow-up studies have been reported, and neither ethanol nor high glucose tolerance trait was observed when cells containing the *SPT15-300* allele were grown on rich media (Baerends et al., 2009). In the present study, five ethanol-tolerant *S. cerevisiae* strains were constructed by exploiting gTME. The ethanol tolerance phenotype was sustained when cells were grown on YPD agar (Fig. 5A). This discrepancy may be due to differential expression of a set of

Table II. Comparison sets and strategies used to identify ethanol tolerance-related genes by comparing expression profiles.

The prefix 'e' represents ethanol challenge. The subscripts indicate that the counterpart is isogenic (i) or unrelated (u) to control. Strains used are in parentheses. C, control strain; T, ethanol-tolerant strain; NA, not available.

^aBased on twofold change.

^bNot specified here due to the variety.

^cPerformed for 175 genes selected from previous studies for an ethanol-tolerant yeast and its parental strain.

^dShowing twofold change at any timepoint during 48-h-long ethanol challenge.

^eCommon between ETS2 and ETS3.

^fRegulated under either shaking or static condition.

genes induced by different *SPT15* alleles (*SPT15-300* and *SPT15-M2* or *-M3*) as shown in the DNA microarray analysis. Most notably, genes involved in the amino acid metabolism including leucine, the elevation of which has been suspected to closely associated with ethanol tolerance conferred by *SPT15-300* (Baerends et al., 2009), were not up-regulated by *SPT15-M2* or *-M3* (Table I). The differential expression cannot be simply explained by the difference in location of point mutations: three of *SPT15-300* (F177S, Y195H, and K218R) clustered in the repeat element 2 (Alper et al., 2006), whereas those of *SPT15-M1-5* scattered on the *SPT15* ORF without overlapping with each other, including the non-conserved N-terminal region of 60 amino acids (Fig. 2). Even a truncated *SPT15* (*SPT15-M1*) was formed. However, it should be noted that an amino acid change(s) was commonly found in the repeat element 2 of *SPT15-M1-5*, suggesting that this domain might be related with ethanol tolerance observed in this study. It would be interesting to determine which amino acids are responsible for ethanol tolerance by reverting mutations to their wild types or shuffling mutations between *SPT15-M1-5*.

We also showed that the enhanced ethanol tolerance conferred by gTME through mutated *SPT15* alleles resulted in 25% increase of ethanol production (Fig. 6). Previously, the effect of enhanced ethanol tolerance generated in various ways such as genomic shotgun (Hong et al., 2010), SGKO screening (Teixeira et al., 2009), genome shuffling (Hou, 2009) and transcription factor overexpression (Hou et al., 2009), was examined by measuring the highest ethanol titer from batch cultures. In these studies, however, the ethanol production was increased by slightly more than 10% compared to the control strains. The contrasting increase in ethanol production between the previous and present studies may be due to different fermentation conditions: most probably, flask culture versus bioreactor culture. Although it is difficult to compare the efficiency of several technologies mentioned above, gTME seems to be an efficient tool to create strains with enhanced ethanol tolerance. In addition, the *SPT15* mutation library constructed in this study may be further used for screening strains with enhanced tolerance to other stresses such as heat, fermentation inhibitors, osmotic pressure, and so on.

We are grateful to Dr. Won-Kee Hur (Seoul National University, Korea) for providing *S. cerevisiae* BY4741 deletion mutant library and to Drs. J. B. Park (Ewha Womans University, Korea) and Y. C. Park (Kukmin University, Korea) for helpful comments especially in fermentation. This research was supported by Pioneer Research Center Program through the National Research Foundation of Korea funded by Ministry of Education, Science and Technology (No. 2009-0081512 and No. 2007-2005047).
